## Models for data with too many zeros: Fish in Florida ranches' wetlands

Species counts are particularly difficult to analyze because commonly, zero inflation results from having far more zeros that what would be expected for Poisson or Negative Binomial distributions. We use data collected by Bohlen *et al.* (2014) aimed at understanding the effect of hydrology on species abundance to evaluate government policies encouraging water retention. They used a stratified random sampling method to gather data on abundance of several organisms in wetlands within four ranches in Highlands and Okeechobee Counties in Florida, USA. Here, we focus on the abundance of fish (Figure 1). For this analysis we ignore the hierarchical nature of the sampling among wetlands within ranches.

Figure 1. Above: View of one of the sampled wetlands. Below: Female and male Mosquito fish (Gambusia affinis), one of the species found in our samples.

Bohlen *et al.* (2014) proposed hypotheses on the shape of the responses of organisms to wetland water depth; in particular they expected a unimodal distribution for fish abundance (Figure 2). They also predicted that fish abundance will vary among ranches because of management history and local attributes.

Figure 2. Hypothesis of change of fish abundance with water depth

Figure 3. Histograms of fish abundance for (i) the whole sample, (ii) those samples where fish were observed, (iii) expected frequency based on a Poisson distribution based on the overall mean, (iv) expected frequency based on a Poisson distribution based on the mean of samples > 0, (v) expected frequency based on a negative binomial distribution based on the overall mean and dispersal parameter = 0.58, (vi) expected frequency based on a negative binomial distribution based on the overall mean and dispersal parameter = 0.58, (vi) expected frequency based on a negative binomial distribution based on a negative binomial dispersal parameter = 100, (viii) expected frequency based on a negative binomial distribution based on the overall mean and dispersal parameter = 0.19. In red the location of the overall mean, in blue that of the data > 0. Data is truncated to occurrences < 20 fish per sample.

## The origin of zeros

The numbers of fish caught per sample was extremely variable. Most frequently no fish were caught, but 70 fish were caught at once in one occasion. A Poisson distribution with the same mean as the one observed in this study expects 297 zeros, not close to the 509 zeros observed. The prediction of 450 from the Negative Binomial with dispersal parameter 0.58 is closer but Zuur *et al.* (2009) caution that ignoring zero inflation biases the standard errors and causes over-dispersion. There are techniques that deal with this excess of zeros, but they require understanding the nature of the zeros. We use the classification described in Martin *et al.* (2005) to classify those encountered in our study.

- 1. Structural zeros: Fish were not present because the habitat was not suitable for them.
- 2. Design errors: Fish were not found because of poor experimental design or sampling practices.
- 3. Observer error: Fish were there but they were not seen.
- 4. Organism error: The habitat was suitable but fish were not there.
- 5. Bad zeros: Sampling outside the species range, for example fish out of water.

Zeros due to design, observer and impossible species range are called false zeros or false negatives and we should do our best to avoid those (Zuur *et al.* 2009). Researchers have little control of organismal error but it can be minimized with better designs. Structural zeros are called positive or true zeros, but these definitions are open to discussion (Martin *et al.* 2005). We

recognize that our study probably includes false negatives, for example, the methods we used did not sample large fish well. We did try to minimize design and observer error by having experienced biologists collect and retrieve the samples.

There are four possible models to analyze our zero-inflated fish data. The difference between the Poisson and negative binomial is that the second allows for additional over-dispersion in the positive (non-zero) part of the data (Zuur et al. 2009). There are also two different ways to consider the zeros: mixture zero-inflated models (known as Zi and Ni models for Poisson and negative binomial distributions, respectively) and two part zero-altered models (Za and Na) (Zuur et al. 2009). Zeros in mixed zero-inflated models are modelled as coming from two different processes: the binomial and the count processes, where the binomial GLM estimates the probability of false zeros versus all other type of data (counts and true zeros). In zero-altered models, the non-zero observations are modelled with a truncated Poisson or negative binomial and therefore the count process does not allow for zeros. In both cases it is possible to use different sets of covariates to explain the occurrence and the counts. You can use AIC criteria to select the most informative model, but we agree with Zuur et al. (2009) that it is better to use biological knowledge to decide among them. In this case, we only use the mixed zero-inflated type of models because we are convinced on the existence of genuine structural zeros. We expect the shallower and the deeper areas in the wetlands to not be as suitable for fish as intermediate depths.

We start by specifying five possible structures for the effect of depth and ranch on fish count. Anything before the | is the structure of the count model i.e. how many fish, while terms after the | refer to the structure of the binomial model i.e. are there fish or not. If the last part is not specified, the default is to use the same structure for both components (i.e. f1 and f2 below are the same). Formulas 1 to 4 assume an interactive effect of depth (as a quadratic variable) and ranch, but f3 assumes the presence of fish in only affected by depth while f4 assumes it is only affected by ranch. F5 assumes an additive effect of depth and ranch, and f6 assume only depth is important in the count and zero models.

```
f1 <-formula(fishct~depth*ranchn+depth2*ranchn)
f2 <-formula(fishct~depth*ranchn+depth2*ranchn | depth*ranchn+depth2*ranchn)
f3 <-formula(fishct~depth*ranchn+depth2*ranchn | depth)
f4 <-formula(fishct~depth*ranchn+depth2*ranchn | ranch)
f5 <-formula(fishct~depth+depth2+ranchn | depth)
f6 <-formula(fishct~depth+depth2 | depth)</pre>
```

Then we decide whether to allocate a Poisson or negative binomial distribution to the count models and end up with the following ten models (notice Zi1 = Zi2 and Ni5 = Ni6).

```
Zil <- zeroinfl(fl,dist="poisson", link="logit", data = dataforstats)
Zi2 <- zeroinfl(f2,dist="poisson", link="logit", data = dataforstats)
Zi3 <- zeroinfl(f3,dist="poisson", link="logit", data = dataforstats)
Zi4 <- zeroinfl(f4,dist="poisson", link="logit", data = dataforstats)
Ni5 <- zeroinfl(f1,dist="negbin", link="logit", data = dataforstats)
Ni6 <- zeroinfl(f2,dist="negbin", link="logit", data = dataforstats)
Ni7 <- zeroinfl(f3,dist="negbin", link="logit", data = dataforstats)
Ni8 <- zeroinfl(f4,dist="negbin", link="logit", data = dataforstats)
Ni8 <- zeroinfl(f4,dist="negbin", link="logit", data = dataforstats)
Ni9 <- zeroinfl(f5,dist="negbin", link="logit", data = dataforstats)
Ni10 <- zeroinfl(f6,dist="negbin", link="logit", data = dataforstats)</pre>
```

We identify model Ni5 as the most plausible in our set using AIC (after removing the redundant formulations).

AICtab(Zi1,Zi3,Zi4,Ni5,Ni7,Ni8,Ni9,Ni10,weights=TRUE,base=TRUE)

AICdAICdfweightN151899.30.0250.8053N171902.43.1150.1710N191907.38.090.0144N181908.28.9170.0093N1101937.738.56<0.001</td>Zi12544.3645.024<0.001</td>Zi32549.7650.414<0.001</td>Zi42559.0659.716<0.001</td>

The summary and statistical model for Ni5 are presented below:

```

Theta = 0.5774 Number of iterations in BFGS optimization: 48 Log-likelihood: -924.6 on 25 Df PCB 6468 - Methods in Experimental Ecology II Pedro F. Quintana-Ascencio, David G. Jenkins & Lina M. Sánchez-Clavijo Spring 2016 03/30/2016

$$P(y_i = \mathbf{0}) = \pi_i + (1 - \pi_i) \times \left(\frac{k}{\mu_i + k}\right)^k$$
$$P(y_i > \mathbf{0}) = (1 - \pi_i) \times fNB(y)$$

 $\mu_i = -\alpha + \beta_1 \times depth + \beta_2 \times depth^2 + \beta_{3 ranch} \times depth + \beta_{4 ranch} \times depth^2$ 

$$\pi=\frac{e^{-\mu_i}}{1+e^{-\mu_i}}$$

$$fNB(y) = P(y_i; k, \mu_i | y_i \ge 0) = \frac{Fac(y_i + k)}{Fac(k) \times Fac(y_i + 1)} \times \left(\frac{k}{\mu_i + k}\right)^k \times \left(1 - \frac{k}{\mu_i + k}\right)^{y_i}$$

See Zuur et al (2009) for the details of the negative binomial function fNB(y); Fac = Factorial.

Notice that none of the parameters of the binomial model are statistically different from zero, so we could instead have favored model Ni7 which has a simpler structure (see below). But still, when we compared the mixed zero-inflated model Ni5 against a model without the binomial portion (using both AIC and the Vuong test), we found significant justification for the inclusion of this structure in the model.

```

The residuals differ slightly between the zero-inflated model (A) and the one without the correction (B). Both indicate larger residual variation for smaller predicted values and smaller residual variation in Pal.

Figure 4. Number of fish +1(in blue) as a function of depth (in cm) by ranch. The size of the symbol is related to its frequency in the sampling. Model Ni5 is depicted in black.

Figure 5 A. Residuals of model Ni5.

Figure 5 B. Residuals of model1.

Figure 6. Overall residuals of model Ni5 and model 1.
